Abstract—Web Services fall under the so-called emerging technologies category and are getting more and more used for Internet applications or business transactions. Since Web Services are often the foundation of large applications, they need to be reliable and robust. So, we propose in this paper, a robustness testing method of stateful Web Services, modeled with Symbolic Transition Systems [1]. We analyze the Web Service observability and the hazard effectiveness in a SOAP environment [2]. Then, we propose a test case generation method based on the two hazards "Using unusual values" and "Replacing /Adding operation names", which are the only ones that can be applied. The Amazon E-commerce Web Service is taken as example.

Key-words: Robustness testing, stateful Web Services, STS, test architecture

I. INTRODUCTION

The Web Service paradigm is now well established in companies for developing business applications. These self-contained components offer many advantages such as, providing interoperability between heterogeneous applications, externalizing functional code in a standardized way, or composing choreography and orchestration processes. Interoperability is ensured by standards proposed by the W3C and the WS-I consortiums. Especially, the WS-I basic profile gathers the SOAP protocol, which models how invoking a Web Service with XML messages, and the WSDL language, which is used to describe Web Service interfaces.

Web Services often constitute the foundation of large and complex applications. Consequently, trustability is an essential criterion which must be taken into account while developing them. Trustability can be achieved only by following quality processes, like the CMMI process (Capability Maturity Model Integration). These processes are based on testing activities performed during the whole software life cycle. Among them, robustness testing is a required step when dealing with Web Services. Indeed, the latter are distributed in nature, and can be used by different and heterogeneous client applications. So, they need to behave correctly despite the receipt of unspecified events, called *hazards*.

The purpose of this paper is to tackle the stateful Web Service robustness. Unlike stateless ones, such services are persistent through a session and have an internal state which evolves over the sequences of operation calls. For instance,

all the Web Services using shopping carts or beginning with a login step are stateful. The Amazon E-commerce Web Service (AWSCommerceService), which is taken as an example in this paper, is one of them. We consider Web Services as *black boxes*, from which only the SOAP messages (requests and responses) are observable (we don't have access to the code). So, we model the Web Service state with a symbolic specification describing the different states, the called operations and the associated data.

Black box Web Service testing faces a challenging issue which concerns the lack of observability, involved by SOAP. A message which is usually directly observable, like a classical response or a fault, is either no more observable or is encapsulated and spread to the client over the SOAP protocol. For instance, according to the SOAP 1.2 specification, exceptions, in object oriented programming, ought to be translated into XML elements called SOAP faults. But, to be observed, this feature needs to be implemented by hand in Web Services.

Consequently, we begin to analyze the Web Service observability in the presence of hazards to determine those which are relevant for testing. And we show that only few hazards are really interesting, because most of them are blocked by SOAP processors and are not given to the Web Service itself. We also analyze the responses obtained. These analysis lead to the test case generation method. This one can be summarized by two main steps. First, the specification is completed to add all the operations which can be called and to model the unexpected behaviors. Then, test cases are constructed from the completed specification, by injecting into paths predefined values, well known for relieving bugs. Test cases are then executed with a specific test platform, which has been implemented in an academic tool.

This paper is structured as follows: Section II provides an overview of the Web Service paradigm. We give some related works about Web Service testing and the motivations of our approach. Section III analyzes the Web Service robustness over the SOAP layer. Section IV describes the testing method: we detail the test case generation and a testing framework. We also describe the results obtained from the Amazon E-commerce Web Service. Finally, Section V gives some perspectives and conclusions.

II. WEB SERVICE OVERVIEW

A. Web Service

Web Services are "self contained, self-describing modular applications that can be published, located, and invoked across the Web" [3]. To ensure and improve Web Service interoperability, the WS-I organization has proposed profiles, and especially the WS-I basic profile [4], composed of four major axes: *the Web Service description* through WSDL (Web Service Description Language), *the serialization of messages* via SOAP (Simple Object Access Protocol [2]), *the Web Service Indexation* in UDDI (Universal Description Discovery Integration) registries and *the Web Service security*, obtained through authentication and encryption protocols.

In this paper, we consider black box Web Services, from which we can only observe SOAP messages. Other messages, such as database connections and the Web Service internal code are unknown. So, the Web Service definition, given below, describes the available operations, the parameter and response types. We also use the notion of SOAP fault. As defined in the SOAP v1.2 protocol [2], a SOAP fault is used to warn the client that an error has occurred. A SOAP fault is composed of a fault code, of a message, of a cause, and of XML elements gathering the parameters and more details about the error. Typically, a SOAP fault is obtained, in object-oriented programming, after the raise of an exception by the Web Service.

Definition II.1 A Web Service WS is a component which can be called by a set of operations $OP(WS) = \{op_1, \dots, op_k\}$, with op_i defined by $(resp_1, \dots, resp_n) = op_i(param_1, \dots, param_m)$, where $(param_1, \dots, param_m)$ is the parameter type list and $(resp_1, \dots, resp_n)$ is the response type list.

For an operation op , we define $P(op)$ the set of parameter value lists that op can handle, $P(op) = \{(p_1, \dots, p_m) \mid p_i \text{ is a value whose type is } param_i\}$. The set of response lists, denoted $R(op)$, is expressed with $R(op) = \{(r_1, \dots, r_n) \mid r_j \text{ is a value whose the type is } resp_j\} \cup \{r \mid r \text{ is a SOAP fault}\} \cup \{\epsilon\}$. ϵ models an empty response (or no response).

The operation op corresponds to a Relation $op : P(op) \rightarrow R(op)$. We denote an invocation of this operation with $r = op(p)$ with $r \in R(op)$ and $p \in P(op)$.

The parameter/response types may be simple (integer, float, String, etc.) or complex (trees, tabular, objects composed of simple and complex types, etc.) and each one is either finite (integer, etc.) or infinite (String, etc.).

We model the Web Service state with STS (Symbolic Transition Systems [1]). STS offer a large formal background (definitions of implementation relations, test case generation algorithms, etc.) and are semantically close to UML state machines. Besides, some tools are proposed to translate UML state machines into STS [5]. An STS is a tuple $\langle L, l_0, Var, var_0, I, S, \rightarrow \rangle$, composed of symbols S : inputs, beginning with "?" are provided to the system, while outputs, (beginning with "!") are observed from it. δ models

the quiescence (no event is observed). An STS is composed of a variable set Var , initialized by var_0 . Each transition $(l_i, l_j, s, \varphi, \varrho) \in \rightarrow$ from the state l_i to l_j , labeled by the symbol s , may update variables with ϱ and may have a guard φ on Var , which must be satisfied to fire the transition.

Furthermore, we denote $(x_1, \dots, x_n) \models \varphi$, the satisfaction of the guard φ according to the values (x_1, \dots, x_n) .

The specification example, given in Figure 2 (with solid lines only), describes a part of the Amazon Web Service devoted for E-commerce (AWSECommerceService), which offers many features such as searching items, looking for item details, creating carts, purchasing, etc. Note that we do not include all the parameters for readability reasons. A symbol table is given in Figure 1. The associated data (isbn) are extracted from the Amazon documentation.

?a	ItemSearch<String AWSAccessKeyID,String SearchIndex,String KeyWords>
?d	ItemLookUp<String AWSAccessKeyID,String RequestID>
?f	CartCreate<String AWSAccessKeyID,String ItemASIN,Integer Quantity>
?h	CartAdd<String AWSAccessKeyID,String ItemASIN,Integer Quantity>
?l	Purchase<String CartID,String CustomerInfos>
!c	ItemSearchResponse<String Errors,String IsValid> [IsValid=="false" && AWSAccessKeyID != "ID"]
!b	ItemSearchResponse<String Items,String IsValid> [IsValid=="true" && AWSAccessKeyID=="ID"]

B. Related work on Web Service robustness testing

There are many research papers concerning Web Services testing, and some of them, focusing on robustness, are summarized below. All of them consider stateless Web Services or BPEL processes. Robustness is then tested by handling WSDL descriptions [6], [7], [8] or by injecting hazards into SOAP messages [9], [10].

In [6], the Web Service robustness is automatically tested from WSDL descriptions. The method uses the Axis 2 framework to generate a class composed of methods allowing to call service operations. Then, test cases are generated with the tool "Jcrasher", from the previous class. Finally, the tool Junit is used to execute test cases. Another method is proposed in [7], which is based on the WSDL analysis to identify what faults could affect the robustness attribute and then test cases were designed to detect those faults. In [8], we also proposed a Web Service robustness testing method, which automatically assesses the stateless Web Service robustness by using WSDL description. The method performs random testing improved with the use of the hazard "Using unusual values". A tool has been developed and tested on real Web Services.

through the SOAP protocol, this is concretely the couple (SOAP processor, Web Service) which is really requested. And we have observed that SOAP processors affect the Web Service observability by generating responses instead of the Web Service itself, when it crashes. The same issue is raised with stateful services. So, we need to separate the SOAP processor behavior to the Web Service one.

The WS-I basic profile enables to differentiate the SOAP faults generated by SOAP processors from those constructed by Web Services. When an exception is raised, the Web Service ought to generate itself a SOAP fault. In this case, the SOAP fault cause is always equal to "RemoteException". Otherwise, SOAP faults are generated by SOAP processors.

We deduced from this analysis that a Web Service operation is robust if it returns a classical response or a SOAP fault whose the cause is equal to "RemoteException". This is formalized in the following definition:

Definition III.1 Let WS be a Web Service. An operation $(resp_1, \dots, resp_n) = op(param_1, \dots, param_m) \in OP(WS)$, op is robust, if $\forall v \in P(op), r = op(v)$ with:

- $r = (r_1, \dots, r_n)$ such as $r_i = resp_i$ or,
- r is a SOAP fault composed of the cause "RemoteException".

B. Stateful Web Service robustness analysis

We analyzed in [8], the hazards based on the operation parameter handling. We studied the following hazards: **Replacing parameter types, Inverting parameter types, Adding/injecting parameter types, Deleting parameter types** and **Using unusual values**. We deduced that the latter is the only one accepted by SOAP processors and really given to Web Services. The other ones are always blocked by SOAP processors and become unnecessary. This hazard, well-known in software testing [12], aims to call an operation $op(param_1, \dots, param_m)$ with values $(p_1, \dots, p_m) \in P(op)$ (each parameter p_i has the type $param_i$). But these predefined values are unusual and may potentially reveal bugs. For instance, null, "", "\$", "*" are some unusual "String" values.

We extend here this study for stateful Web Services. As previously, some hazards are unnecessary because they are blocked by SOAP processors. We have studied the following hazards: **Changing operation name, Replacing /Adding operation name**. Let WS be a Web Service and STS its specification:

- **Changing operation name:** this hazard aims at randomly modifying an operation name $op \in OP(WS)$ to op_modif such as op_modif is not an existing operation ($op_modif \notin OP(WS)$). When this hazard is put into practice, we always receive a SOAP fault composed of the cause "Client", which means that the client request is erroneous. This hazard produces requests which are always blocked by SOAP processors since these ones do not conform the WSDL description. So, because the test cannot be performed, we consider that this hazard is useless,

- **Replacing /Adding operation names:** Let l be a state of the STS specification with outgoing transitions $(l, l_1, "op_1(p_{11}, \dots, p_{m1})", \varphi_1, \varrho_1), \dots, (l, l_n, "op_n(p_{1n}, \dots, p_{mn})", \varphi_n, \varrho_n)$ modeling operation calls. If it exists an operation $(resp_1, \dots, resp_n) = op(param_1, \dots, param_m)$ which is not called from l ($op \notin \{op_1, \dots, op_n\}$), this hazard aims to replace/add the call of an operation $op_i \in \{op_1, \dots, op_n\}$ by op . Since this hazard satisfies the Web Service WSDL description, it is not blocked by SOAP processors. However, when op is called, only a response from op can be received. So, we cannot just replace/add a name in the specification. For instance, if we replace the operation "itemSearch" to "AddCard", in our example of Figure 2, we will not receive a response from "ItemSearch" but from "AddCard" while testing. If the operation op is robust, as defined in the section III-A, the expected response from op is either a classical response (r_1, \dots, r_n) where r_i has the type $resp_i$, or a SOAP fault whose the cause is "RemoteException".

This hazard involves to complete the specification on the operation calls for each state. This modification is detailed in the test case generation section (see IV-B).

It exists of course other hazards based on the SOAP message modification, such as replacing the port name or modifying randomly the SOAP message. These hazards are usually used for testing Web Service compositions in order to observe partner behaviors. Concerning stateful Web Services, either the message random modification is equivalent to a previous hazard (parameter, operation modification) or gives an inconsistent SOAP message which is blocked by SOAP processors. Note that the WS-I basic profile does not allow overloading of operation so this hazard is not considered.

Consequently, the most relevant hazards for stateful Web Services are, calling operations with "using unusual values" and "replacing /adding operation names".

IV. STATEFUL WEB SERVICE ROBUSTNESS TESTING METHOD

Like many testing methods, we first set an assumption on the Web Service observability to improve the test efficiency. We suppose that Web Service operations are not quiescent (return non empty responses). Indeed, without response that is without observable event, we cannot conclude whether the operation is correct or crashes and is faulty.

Web Service observable operation hypothesis: We suppose that each Web Service operation, described in WSDL files, are not quiescent.

The test case generation method is illustrated in Figure 4. This one is mainly based on the two hazards "Using unusual values" and "Replacing /Adding operation names" previously described. First, the specification states are completed on the operation calls to apply the hazard "Replacing /Adding operation names". It is also completed to model the incorrect behavior (incorrect responses) and the state quiescence (states blocked after a timeout). So, test cases, generated from the

Fig. 4. Test case generation

```

<type id="String">
  <val value=null />
  <val value="" />
  <val value=" " />
  <val value="$" />
  <val value="*" />
  <val value="%" />
  <val value="hello" />
  <val value=RANDOM" />
  <!-- a random String-->
  <val value=RANDOM(8096)" />
</type>
(a) V(String)

<type id="tabular">
  <val value=null />
  <!-- an empty tabular-->
  <val value= null null />
  <!--tabular
  composed of two empty elts-->
  <val value= simple-type />
</type>
(b) V(tabular)
  
```

Fig. 5. Unusual value set V

complete specification, will describe both the correct behavior which will lead to a pass verdict and also the incorrect behavior which will lead to a fail verdict (faulty implementation). Taking into account quiescence in Web application testing is also required since these ones may hang or crash without returning a response. According to the observability hypothesis previously given, we consider that Web Services are faulty when quiescence is observed (when they are observed as blocked after a timeout).

Test cases are generated with the "Using unusual values" hazard which is expressed by a set of values V . This set contains for each type, an XML list of values that we use for calling operations. We use predefined values well known in software testing for relieving bugs (section III-A).

We denote $V(t)$ the set of specific values for the type t which can be a simple type or a complex one. Figures IV, and IV show some values used for the types "String" and for "tabular" of "simple-type". For a tabular composed of String elements, we use the empty tabular, tabulars with empty elements and tabulars of String constructed with $V(String)$.

In the following, we develop the specification completeness, the test case generation and the elaboration of the final verdict.

A. Specification Completeness

As stated previously, we complete the specification to apply the hazard "Replacing /Adding operation name" and to add the incorrect Web Service behavior.

Let WS be a Web Service and STS be its specification, with $STS = \langle L, l_0, Var, var_0, I, S, \rightarrow \rangle$. STS is completed

by using the following steps:

- 1) **Adding "pass" verdict into the final states**, which means that to reach this final state, a correct behavior has to be executed,
- 2) **Operation call completion**: each state is completed to take into account the hazard "Replacing /Adding operation names". $\forall l \in L$ such as l has the outgoing transitions $(l, l_1, "op_1(p_{11}, \dots, p_{m1})", \varphi_1, \varrho_1), \dots, (l, l_n, "op_n(p_{1n}, \dots, p_{mn})", \varphi_n, \varrho_n)$, we add: $\forall (resp_1, \dots, resp_k) = op_i(param_1, \dots, param_m) \in OP(WS) / \{op_1, \dots, op_n\}, (l, l_i, op_i(p_{i1}, \dots, p_{im}), \emptyset, \emptyset), (l_i, l, op_i_return(r), \varphi_i, \emptyset)$, with $\varphi_i = [(r == (c, soap_fault), c = RemoteException)] \vee (r = (r_1, \dots, r_k) \text{ has the type } (resp_1, \dots, resp_k))]$. If, from a state, an unspecified operation is called and if either the obtained response has the expected type or the response is a SOAP fault whose the cause is "RemoteException", then the Web Service has accepted the request and is robust (see Section III-B). Finally, it returns to the state preceding the request,
- 3) **Incorrect behavior completion**: for each state, the specification is completed on the incorrect response set: $\forall l \in L$ such as l has the outgoing transitions $(l, l_1, "op_return(r_1)", \varphi_1, \varrho_1), \dots, (l, l_n, "op_return(r_n)", \varphi_n, \varrho_n)$, we add: (1) $(l, fail, \delta, \emptyset, \emptyset)$, (2) $(l, fail, "op_return(r)", \varphi, \emptyset)$, with $\varphi = [\neg(\varphi_1 \vee \dots \vee \varphi_n)]$. (1) δ models the state quiescence (blocking state). (2) If the called operation does not return a specified response, then the Web Service behavior is incorrect in the presence of hazards and the operation is not robust.

The STS of Figure 2 illustrates a complete specification. The dotted transitions represent the call of unspecified operations. Those illustrated with dashed lines model incorrect responses. The new symbol table is given in Figure 3.

B. Test case generation

Prior to describe the test case generation, we define a test case with:

Definition IV.1 Let WS be a Web Service modeled by $STS = \langle L, l_0, Var, var_0, I, S, \rightarrow \rangle$. A test case T is an STS tree where each final state is labeled by a verdict in $\{pass, fail\}$. Branches are labeled either by $(op(v), \varphi, \varrho)$ or by $(op_return(r), \varphi, \varrho)$ or by δ where:

- $v \in P(op)$, is a list of parameter values used to invoke op ,
- $r = (c, soap_fault)$ is a SOAP fault composed of the cause c , or $r = (r_1, \dots, r_m)$ is a response
- φ is a guard and ϱ an update on Var ,
- δ represents the state quiescence.

Test cases are constructed by using the following algorithm. This one generates traces in which hazards are injected. For a transition modelling the call of the operation op , the algorithm constructs a preamble to reach this transition (lines 4-5). A value set over V is constructed according the parameter types

of op . If these ones are complex (tabular, object, etc.), we compose them with other types to obtain the final values. We also use an heuristic to estimate and eventually to reduce the number of tests according to the number of tuples in $Value(op)$. Constraint solvers [13], [14] are also used to generate the values allowing the full execution of preambles. We add $op(v_1, \dots, v_m)$ after the preamble to call the operation op with unusual values (v_1, \dots, v_m) (line 9). Then, we concatenate all the executable traces reaching a final state labeled by a verdict (lines 10-11) (traces whose the conditions can be satisfied).

The constraint solvers construct values satisfying the guards of a specification path and hence satisfying its execution. We use the solvers [13] and [14] which works as external servers that can be called by the test cases generation algorithm. The solver [14] manages "String" types, and the solver [13] manages most of the other simple types. Where the data type is complex (object, etc.), we need to transform them into a set of simple types before using constraint solvers.

Figure 6 illustrates a test case example, obtained from the complete specification of Figure 2. The operation "ItemLookUp" is called instead of "ItemSearch". The service is robust if it responds with an expected response type or with a SOAP fault composed of the cause "RemoteException" and if it is always possible to use the operation "ItemSearch" to reach a "pass" state (correct behavior). Otherwise, the verdict is "fail" and the Web Service is not robust.

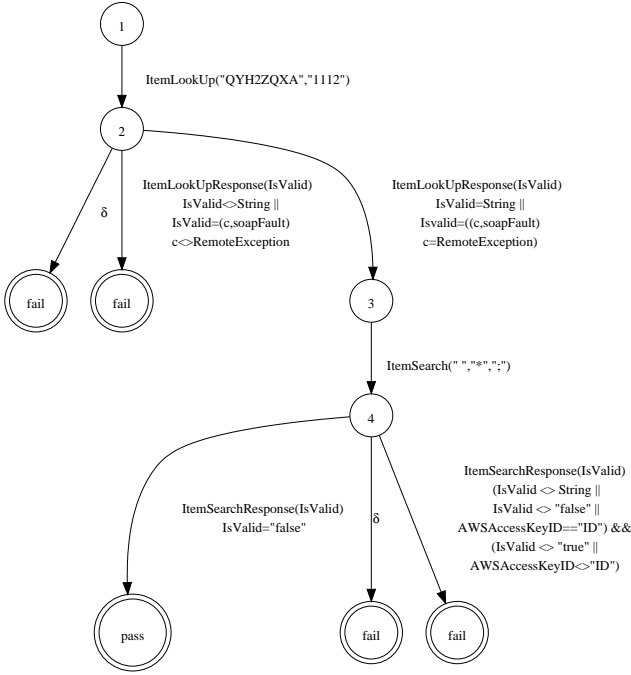

Fig. 6. Test case

C. Test case execution and verdict

Test cases are generated and then executed with the testing platform, illustrated in Figure 7, which as been implemented

Algorithm 1: Test case generation

```

1 Testcase(STS): TC;
2 foreach transition  $t = (l_k, l_{k+1}, ?e_k, \varphi_k, \varrho_k)$  labeled
3 by an input  $?e_k = op(param_1, \dots, param_m)$  do
4   path  $p = DFS(l_0, l_k)$ ; Solving(p);
5    $Value(op) = \{(v_1, \dots, v_m) \in$ 
6      $V(param_1) \times \dots \times V(param_m)\}$ ;
7   foreach  $(v_1, \dots, v_m) \in Value(op)$  do
8      $TC = TC \cup tc$  with;
9      $tc = p; (l_k, l_{k+1}, op(v_1, \dots, v_m), \varphi_k, \varrho_k); t;$ 
10    with  $t = t'_j; postambule; verdict$  such as
11     $\forall t' = (l_{k+1}, l_j, a_j, \varphi_j, \varrho_j) \in \rightarrow, (v_1, \dots, v_m) \models \varphi_j,$ 
12     $postambule = DFS(l_j, l_t)$  is a path between  $l_j$ 
13    and a final state  $l_t \in L$  and  $verdict$  labeled in  $l_t$ ;
14    Solving(postambule);
15  end
16 end
17 Solving(path p):p;
18  $p = (l_0, l_1, a_0, \varphi_0, \varrho_0) \dots (l_{k-1}, l_k, a_{k-1}, \varphi_{k-1}, \varrho_{k-1})$ ;
19 foreach  $(l_i, l_{i+1}, a_i, \varphi_i, \varrho_i)$  with  $i > 0$  do
20    $(x_1, \dots, x_n) = solver(\varphi_i)$  //solving of the guard  $\varphi_i$ 
21   composed of the variables  $(X_1, \dots, X_n)$  such as
22    $(x_1, \dots, x_n) \models \varphi_i$ ;
23    $\varrho_{i-1} = \varrho_{i-1} \cup \{X_1 = x_1, \dots, X_n = x_n\}$ ;
24 end
  
```

Fig. 7. Test platform

in an academic tool. The tester corresponds to a Web Service which receives the URL of the Web Service to test and its specification. It constructs test cases as described in section IV-B, and then executes them successively. Once test cases are executed, it analyzes the obtained responses and finally gives a test verdict.

The tester executes each test case by traversing the test case tree: it successively calls an operation with parameters and waits for a response while following the corresponding branch. If a branch is fully executed, a local verdict "pass" or "fail" is obtained. We also set that quiescence (blocking state after a timeout) is observed after a timeout of 60s. For a test case t , we denote the local verdict $trace(t) \in \{\text{pass}, \text{fail}\}$. The final verdict is given by:

Definition IV.2 Let WS be a Web Service and TC be a test case set. The verdict of the test over TC , denoted

	09/03	09/10
Number of tests	100	100
Using unusual values	75	75
Replacing/Adding operation names	25	25
Fails	34	34
Unspecified messages	28	28
Unspecified SOAP faults	6	6

Fig. 8. Test results on the Amazon AWSECommerceService services

$Verdict(WS)/TC$ is

- "pass", if for all $t \in TC$, $trace(t) = pass.$,
- "fail", if it exists $t \in TC$ such as $trace(t) = fail$.

We applied this method and executed test cases on two versions of the AWSECommerceService service (see Figure 8). Roughly 30 percent of the tests have provided unexpected responses. With the hazard "Using unusual values", and despite that all the tests satisfy the WSDL description, we have sometimes received SOAP faults composed the cause "Client", meaning that the request is incoherent. However, these results may be altered of account of security rules (firewalls, etc.). We have also received unspecified messages corresponding to errors composed of a wrong cause. For instance, we have received the response "Your request should have at least 1 of the following parameters: AWSAccessKeyId, SubscriptionId." whereas these two parameters are correct, when we have called "CartAdd" with a quantity equal to "-1", or when we have searched a "Book" type instead of the "book" one. We have also observed the same situation with the hazard "Replacing /Adding operation names" only when the operation "CreateCard" is replaced by another one. So, according to our robustness definition, this service seems to crash and to be not robust. More details can be found in [15].

V. CONCLUSION

The WS-I basic profile, which gathers the SOAP protocol and the WSDL language among others, reduces the Web Service observability. This lack of observability leads to new issues for robustness testing. We have shown, in this paper, that few hazards can be really used (only the hazards "Replacing name/Adding operation" and "Using unusual values") and that the Web Service behavior needs to be separated from the SOAP processor one to finally conclude on the Web Service robustness. We have proposed a robustness testing method which takes a symbolic specification and applies the previous hazards by completing the specification behavior and by injecting unusual values into the test cases.

Some perspectives can be considered, especially in relation to the set of unusual values V . This one can be manually modified but stays static during the test case generation. It could be more interesting to propose a dynamic analysis of the parameter types to build a list of the most adapted values for each Web Service. Furthermore, to avoid a test case explosion, the values of V are randomly chosen. A better solution would be to choose these parameters according to the operation description. It could be also interesting to analyze the values

raising the more errors while testing in order to set a weighting at each of them.

We have also assumed that the messages sent and received by Web Services are only SOAP messages. However, services can be connected to other servers, as databases. So, a Web Service could be considered as a gray box from which, any type of message could be observed.

Finally, this work can lead to the study of security testing which covers many aspects such as integrity, authentication or availability which depends on robustness. As this method, an observability analysis is required to determine the kind of security issues which can be detected and the responses from which a verdict can be established. A new specification completion should be proposed too.
